

Inverse-Leibniz cubic calculation

Selected contraction

$$h \longmapsto A = -hD_\alpha|_{\mathcal{R}}$$

Cyclic source $g_3(0)$ and chosen spectrum

$$\chi_A(S) = (S + 2)^2 q(S)$$

Normalized and marked data

$$A(E) = -2E$$

$$D_\alpha A^n E = 2(-2)^n dE$$

$$\mathcal{L}_{\text{res}} = \mathbb{C}\beta, \quad T_{\text{resp}} = \mathbb{C}\alpha$$

Full recurrent spectrum depends on h ;
the common spectral divisor is $S + 2$.

The response is natural under
strict resonance-faithful comparisons.

Normalized internal tilts keep the E -rail in the fixed envelope.
Ordinary quasi-isomorphism can erase the marked boundary-response pair.
